Here we examine variation in codon usage patterns of endogenous and exogenous genes in the yeast Lachancea kluyveri. Previous studies indicate that the left arm of chromosome C, or $\sim 10\%$ of the L. kluyveri genome, is the result of an large introgression of exogenous genes. Thus, the L. kluyveri genome provides an opportunity to study the adaptation of these exogenous to a novel cellular environment and estimate how the genetic load of these genes changes over time. In order to quantiatively describe L. kluyveri's codon usage environment, we fitted a bayesian, mechanistic model of codon usage bias evolution, ROC-SEMPPR, to L. kluyveri's endogenous gene in order to estimate the strength of mutation bias and selection on codon usage. We then compared these parameter estimates to those we obtained by fitting ROC-SEMPPR to L. kluyveri's exogenous genes, which provides a biased estimate of the ancestral environment of the exogenous genes. Our results indicate the differences in codon usage between L. kluyveri's endogenous and exogenous genes are largely due to differences in mutation bias, rather than selection. Estimating mutation and selection parameters separately for the endogenous and exogenous genes improved our ability to predict empirical estimates of protein synthesis by 17% and avoided errors in identifying L. kluyveri's selectively favored or 'optimal' codons. By comparing our mutation and selection parameters to those estimated for other yeast species, we identified Eremothecium qossypii as the most likely source of L. kluyveri's exogenous genes. Using these parameters and available estimates of mutation rates in yeast, we estimated the age of the introgression to be on the order of 6×10^8 generation. Finally, we estimated the genetic load of the exogeneous genes both at the time of introgression and currently. In summary, our work shows the advantage of using mechanistic models that separate the effects of selection and mutation on codon usage.

36 Introduction

Synonymous codon usage patterns often varies within a genome and between taxa, reflecting differences in mutation bias, selection, and genetic drift. The signature of mutation bias is largely determined by the organism's internal or cellular environment, such as their DNA repair genes or UV exposure. The signature of selection on codon usage is also largely determined by an organism's cellular environment, such as its tRNA species, their copy number, and post-transcriptional modifications. In contrast, the strength of selection on the codon usage of an individual gene is largely determined by its expression level which, in turn, is also largely determined by the organism's external environment. In turn, the efficacy of selection on codon usage is a function of the organism's effective population size N_e which, in turn, is largely determined by its external environment. Thus, disentangling the evolutionary forces responsible for the patterns codon usage bias (CUB) encoded in an species genome, should provide biologically meaningful information about the lineage's historical cellular and external environment.

In order to disentangle the forces of mutation, selection, and drift behind CUB we utilize a quantitative, population genetics based approach after Bulmer [1991]. More specifically, we utilize the Ribosome Overhead Cost (ROC) version of Shah and Gilchrist [2011] of the more general Stochastic Evolutionary Model of Protein Production Rates (SEMPPR) introduced in Gilchrist [2007] using the R software package AnaCoDaLanderer et al. [2018]. The population genetics mutation-selection-drift framework of ROC SEMPPR allows us to quantitatively describe the environment in which genes evolve with respect to mutation bias and selection bias, which are the codon specific selection terms implicitly scaled by N_e and explicitly scaled by the average expression level of a gene [See Gilchrist et al., 2015a, for more details], using only coding sequenced data. Here we expand upon our previous work with ROC to accommodate the additional complications of gene introgression.

Most studies implicitly assume that synonymous codon usage of a genome is reflects the single mutational and selective cellular environment of the organism. However, any introgressed genes, whether the result of hybridization or horizontal gene transfer, should
carry the signature of the exogenous cellular environment whence they came and, in turn,
impose a genetic load on the recipient lineage. The magnitude of the exogenous genes'
genetic load on the recipient or endogenous lineage should increase as the mutation and
selective environments differ between the donor and recipient lineages as well as with the
expression level of the genes in the recipient cells. Thus codon usage patterns likely play a
critical role in the rates of introgression between lineages and, as a result, can serve as an
important source of information about such events.

To illustrate these ideas, here we analyze the synonymous codon usage of the genome of 71 Lachancea kluyveri, the earliest diverging lineage of the Lachancea clade. The Lachancea 72 clade diverged from the Saccharomyces clade about 100 Mya ago, predating Saccharomyces 73 most recent genome duplication. Since its divergence from the other Lachancea, L. kluyveri has experienced a large introgression of exogenous genes, replacing the ~ 500 on the left arm of L. kluyveri's C chromosome. This introgression of exogenous genes was previously identified by its $\sim 13\%$ elevation in GC content content relative to L. kluyveri's remaining $\sim 5,000$ endogenous genes [Payen et al., 2009, Friedrich et al., 2015]. Taking into account the different signatures of mutation bias and selection bias of these endogenous and exogenous sets of genes substantially improves our ability to predict present day protein synthesis rate ϕ . It also allows us to identify E. qossypii as the most likely source of the introgressed genes out of the 38 yeast lineages with sequenced genomes, estimate the age of the introgression to be on the order of 0.2-1 Mya, hypothesize about the genetic load of these genes, both at the time of introgression and now, as well as make predictions about the CUB of the introgressed genes will evolve in the future.

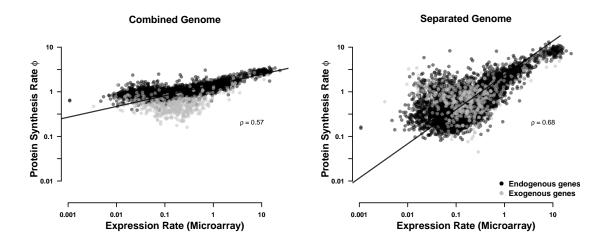

Figure 1: Comparison of predicted protein synthesis rate ϕ to Microarray data from Tsankov et al. [2010] for (a) the combined genome and (b) the separated endogenous and exogenous genes. Endogenous genes are displayed in black and exogenous genes in red. Black line indicates type II regression line.

$m_{^{36}}$ Results

87 L. kluyveri's Genome Contains Signatures from Two Cellular En-

$oldsymbol{^{88}}$ vironments

We used our software package AnaCoDa [Landerer et al., 2018] to compare model fits of ROC SEMPPR to the entire L. kluyveri genome and its genome separated into two sets of 4,864 endogenous and 497 exogenous genes. AIC values (Δ AIC = 75,462; Table 1) strongly support the hypothesis that the L. kluyveri genome consists of genes with two different and distinct patterns of codon usage bias. We found additional support for this hypothesis when we compared our predictions of gene expression to empirically observed values. Specifically, the correlation between our predictions and observed values improved by almost 20%, from $\rho = 0.57$ to 0.68 (Figure 1).

₉₇ Differences in the Endogenous and Exogenous Codon Usage

To better understand the differences in the endogenous and exogenous cellular environments, we compared our parameter estimates of mutation bias ΔM and selection $\Delta \eta$ for the two 99 sets of genes. Our estimates of ΔM for the endogenous and exogenous genes were negatively 100 correlated ($\rho = -0.49$), indicating weak concordance of $\sim 5\%$ between the two mutation 101 environments (Figure 2). For example, the endogenous genes show a mutational preference 102 for A and T ending codons in $\sim 95\%$ of the codon families. In contrast, the exogenous genes 103 display an equally consistent mutational preference towards C and G ending codons (Table 104 S1). As a result, only the two codon amino acid Phenylalanine (Phe, F) has the same rank 105 order for the endogenous and exogenous ΔM values.

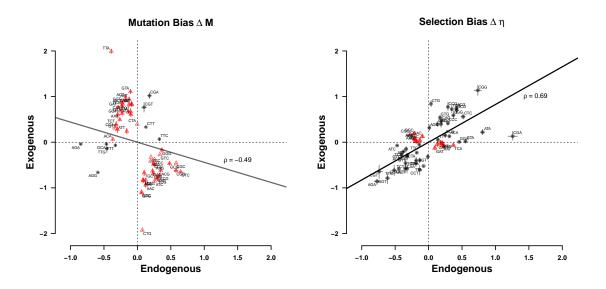

Figure 2: Comparison of (a) mutation bias ΔM and (b) selection bias $\Delta \eta$ parameters for endogenous and exogenous genes. Estimates are relative to the mean for each codon family. Black dots indicate ΔM or $\Delta \eta$ parameters with the same sign for the endogenous and exogenous genes, red dots indicate parameters with different signs. Black line shows the type II regression. Dashed lines mark quadrants.

Our estimates of $\Delta \eta$ for the endogenous and exogenous genes were positively correlated $(\rho = 0.69)$, indicating increased concordance of $\sim 53\%$ between the two selection environments (Figure 2). We find that the strength of selection within a codon family differs between

106

gene sets, causing a change in rank order. Nevertheless, the endogenous genes only show a selection preference for C and G ending codons in $\sim 58\%$ of the codon families. In contrast, the exogenous genes display a strong preference for A and T ending codons in $\sim 89\%$ of the codon families.

The difference in codon preference between endogenous and exogenous genes is striking. 114 Our estimates of the optimal codon differ in nine cases between endogenous and exogenous 115 genes (Table S2). Fits to the complete L. kluyveri genome reveal that the relatively small 116 exogenous gene set has a disproportional effect on the model fit. We find that the complete 117 L. kluyveri genome is estimated to share the mutational preference with the exogenous genes 118 in $\sim 78\%$ of codon families with discordance between endogenous and exogenous genes. In 119 two cases, Isoleucine (Ile, I) and Arginine (Arg, R), the strong discordance in mutation 120 preference results in a estimated codon preference in the complete L. kluyveri genome that 121 is not reflected by either endogenous nor exogenous genes. 122

The impact of the small exogenous gene set on the fit to the complete L. kluyveri genome is less prevalent in our estimates of selection bias $\Delta \eta$ but still strong. We find that the complete L. kluyveri genome is estimated to share the selection preference with the exogenous genes in $\sim 60\%$ of codon families with discordance between endogenous and exogenous genes. Therefore, it is important to recognize and treat endogenous and exogenous genes as separate sets to avoid the inference of incorrect synonymous codon preferences.

Determining Source of Exogenous Genes

We combined our estimates of mutation bias (ΔM) and selection bias $(\Delta \eta)$ with synteny information and searched for potential source lineages of the introgressed region. We examined 38 yeast lineages of which two (*Eremothecium gossypii* and *Candida dubliniensis*) showed a strong positive correlation in codon usage (Figure 3).

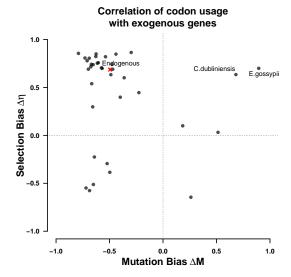

Figure 3: Correlation of ΔM and $\Delta \eta$ of the exogenous genes with 38 examined yeast lineages. Dots indicate the correlation of ΔM and $\Delta \eta$ of the lineages with the endogenous and exogenous parameter estimates. All regressions were performed using a type II regression.

The endogenous L. kluyveri genome exhibits codon usage very similar to most yeast lineages examined, indicating little variation in codon usage among the examined yeasts (Figure S1). Four lineages show a positive correlation for ΔM and $\Delta \eta$ with the exogenous genes and have a weak to moderate positive correlation in selection bias with the endogenous genes; but, like the exogenous genes, tend to have a negative correlation in ΔM with the endogenous genes.

Comparing synteny between the exogenous left arm of chromosome C, and *E. gossypii* and *C. dubliniensis* as well as closely related yeast species we find that *E. gossypii* displays the highest synteny coverage (Figure S2, S3). *C. dubliniensis*, even though it displays similar codon usage does not show synteny with the exogenous region. Furthermore, the synteny relationship between the exogenous region and other yeasts appears to be limited to the Saccharomycetacease group(Figure S3). Given these results, we conclude that the *E. gossypii* lineage is the most likely source of the introgressed exogenous genes.

147 Estimating Introgression Age

We estimated the introgression assuming that $E.\ gossypii$ is still representative of the mutation bias of its ancestral source lineage at the time of the introgression. We infer the age of the introgression to be on the order of $6.2 \pm 1.2 \times 10^8$ generations. $L.\ kluyveri$ experiences between one and eight generations per day, we therefore expect the introgression to have occurred between 205,000 to 1,600,000 years ago. This estimates the introgression to be older than previous assumed Friedrich et al. [2015]. However, our estimates are likely overestimates as they assume a purely neutral decay.

We also estimated the persistence of the signal of the foreign cellular environment. Assuming that differences in mutation bias will decay more slowly than differences in selection bias, we predict that the ΔM signal of the source cellular environment will have decayed to be within one percent of the *L. kluyveri* environment within about $5.4\pm0.2\times10^9$ generations.

Genetic Load of the Exogenous Genes

Estimates of selection bias for the exogenous genes show that, while well correlated with 160 the endogenous genes, only nine amino acids share the optimal codon. Exogenous genes 161 are therefore expected to represent a significant reduction in fitness, or genetic load for L. 162 kluyveri. As the introgression occurred before the diversification of L. kluyveri and has 163 become fixed throughout all populations, we are left without the original chromosome arm 164 [Friedrich et al., 2015]. Using our estimates of ΔM and $\Delta \eta$ from the endogenous genes, we 165 estimate the genetic load of the exogenous genes relative to an expected gene set. We define 166 genetic load as the difference between the fitness of an expected, replaced endogenous gene 167 and the exogenous gene relative to drift $s \propto \phi \Delta \eta$ (See Methods for details). 168

We estimate the genetic load of the exogenous genes at the time of introgression (Figure 4a) and currently (Figure 4b). We scale the difference in the efficacy of selection on codon usage between the donor lineage and L. kluyveri using a linear scaling factor κ . As $\Delta \eta$ is defined as $\Delta \eta = 2N_e q(\eta_i - \eta_j)$, we can not distinguish if κ is a scaling on protein synthesis

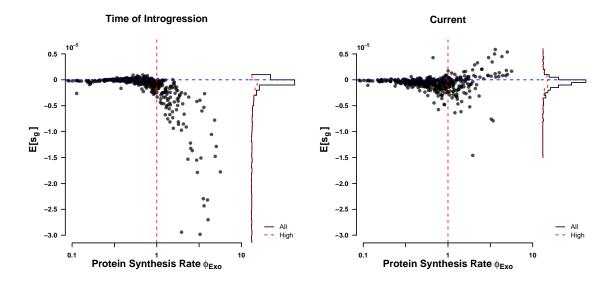

Figure 4: Fitness burden $\Delta s N_e$ (a) at the time of introgression ($\kappa = 5$), and (b) currently ($\kappa = 1$).

rate ϕ , effective population size N_e , or the value of an ATP q[?Gilchrist et al., 2015b]. We predict that only some low expression genes ($\phi < 1$) were weakly exapted at the time of the introgression (Figure 4a). High expression genes ($\phi > 1$) are predicted to carry the highest genetic load in the novel cellular environment. These highly expressed genes also show the greatest rate of adaptation to the L. kluyveri cellular environment (Figures 4a, S5).

Discussion

In order to study the effects of introgression and the resulting mismatches in codon usage in 179 the L. kluyveri genome, we used ROC SEMPPR, a mechanistic model of codon usage bias 180 evolution grounded in population genetics. We show that the L. kluyveri genome contains 181 two distinct signatures of cellular environments, its own endogenous and the introgressed 182 exogenous environments. By fitting ROC SEMPPR separately to L. kluyveri's endogenous 183 and exogenous sets of genes we generate a quantitative description of their signatures of 184 mutation bias and natural selection for efficient protein translation. Our results indicated 185 that the difference in GC content between endogenous and exogenous genes mostly to dif-186

ferences in mutation bias but we also showed that the strength of selection within a codon family differs between the gene sets, causing changes in rank order within codon families. 188 The small number of exogenous genes ($\sim 9\%$ of genes) can have a disproportional impact on 189 our estimates of ΔM and $\Delta \eta$ when fitting ROC SEMPPR to the entire L. kluyveri genome. 190 Without recognizing the difference in codon preference our estimates would not have been 191 reflective of the actual codon usage of the L. kluyveri genome but of a relatively small in-192 trogressed gene set. While this may be surprising, it highlights the importance to recognize 193 differences in codon usage within a genome. Furthermore, our results indicate that we can 194 attribute the increased GC content in the exogenous genes mostly to differences in mutation 195 bias favoring G/C ending codons rather than a novel selective force. 196

The separation of the endogenous and exogenous genes improves our estimates of protein 197 synthesis rate ϕ by 17% relative to the full genome estimate ($\rho = 0.59$ vs. $\rho = 0.69$, 198 respectively). Furthermore, we find that the variation in our estimates of ϕ is more consistent 199 with the current understanding of gene expression (compare Figure 1a and b). Interestingly, 200 the small variation in ϕ estimates may serve as an indicator for the presents of the signature of 201 multiple cellular environments in future work. In the case of the L. kluyveri genome, finding a 202 severe mismatch in ΔM causes ϕ values for low expression genes ($\phi < 1$) to increase towards 203 the inflection point where the dominance of mutation gives way to selection. In the case of 204 the two codon amino acids, the inflection point represents the point at which mutation and 205 selection are contributing equally to the probability of a codons occurrence. We find this 206 inflection point around $\phi = 1$ for most amino acids (Figure S6). However, ROC SEMPPR 207 assumes that estimates of ϕ follow a log-normal distribution with an expected value $E[\phi] = 1$. 208 This assumption allows us to interpret $\Delta \eta$ as the strength of selection relative to drift (sN_e) 209 for a codon in a gene with the average protein synthesis rate $\phi = 1$. However, tying the 210 mean and standard deviation of the prior distribution together. Therefore, an increase in 211 ϕ for low expression genes has to be meet with a decrease of ϕ for high expression genes, 212 reducing the overall variance in ϕ (see Gilchrist et al. [2015b] for details). 213

The introgressed exogenous genes reflect a foreign cellular environment. Since codon 214 usage is a reflection of this environment we attempted to utilize it to find a potential source 215 lineage. Interestingly, we did not find Lachancea thermotolerance, a thermophilic lineage 216 closely related to L. kluyveri, as a potential candidate. While L. thermotolerance does have 217 a strong synteny relationship with L. kluyveri, it does not show similarity in codon usage with 218 the exogenous genes and does not share the increased GC content. The identified E. qossypii 219 lineage stands out as it does not share the same similarity in mutation bias and selection bias 220 with the endogenous genes as most other examined yeast lineages (Figure 2). In general, 221 the inference of synteny relationships between the exogenous region and C. dubliniensis and 222 E. qossypii as well as closely related species showed that synteny relationship is limited to 223 the Saccharomycetaceae clade (Figure S3b). The E. qossypii lineage showed the highest 224 syntenty coverage and is the only species with similar codon usage. E. qossypii is also the 225 only species examined with a GC content > 50% like it is observed in the exogenous region. 226 The synteny coverage extends along the whole exogenous regions with the exception to the 227 very 3' and 5' end of the region. The lack of synteny at the ends of the region also coincides 228 with a drop in GC content, potentially indicating remains of the original replaced region 229 or increased adaptation. The ancestral introgressed region may have also broken up in E. 230 qossypii as we find non overlapping synteny with chromosomes VI and V as well as have indication that the C chromosome of L. kluyveri very robust to recombination events [Payen et al., 2009, Vakirlis et al., 2016]. Payen et al. [2009] found that the exogenous region shows 233 a low rate of recombination and a lack of transposable elements. This may as well be due the 234 difference in GC content as recombination rate decreases with dissimilarity between genomic 235 regions. This also provides a hypothesis why such a large scale introgression has reached 236 fixation before being broken up by recombination. 237

With *E. gossypii* identified as potential source lineage of the introgressed region, we inferred the time past since the introgression occurred using our estimates of mutation bias ΔM . The ΔM estimates are well suited for this task as they are free of the influence of

selection and unbiased by N_e and other scaling terms, which is in contrast to our estimates of $\Delta\eta$ [Gilchrist et al., 2015b]. Our estimated time since introgression of 6×10^8 generated 242 ations is ~ 10 times longer time than a previous estimate by Friedrich et al. [2015] of a 243 minimum of 5.6×10^7 generations . As we assumes all mutations are neutral our estimate 244 is very conservative, potentially better interpreted as an upper boundary in the time since 245 introgression. Our estimate also depend on the assumption that the E. qossypii cellular 246 environment reflects its ancestral environment at the time of the introgression. If the the 247 ancestral mutation environment was more similar to the L. kluyveri environment at the time 248 of the introgression than the E. gossypii environment is today, we would overestimate this 249 time. On the other hand, we would underestimate the time since introgression if the two 250 cellular environments were more dissimilar. We could have attempted to reconstruct the 251 ancestral state of E. qossypii, however, as methods for ancestral state reconstruction are 252 phenomenological, assumptions would be unclear. 253

When estimating the fitness consequences of the introgression we had to make three as-254 sumptions since the introgression has reached fixation. 1) The replaced endogenous genes 255 and the new exogenous genes shared the same amino acid composition. 2) The current 256 L. kluyveri cellular environment is reflective of the cellular environment at the time of the introgression. 3) As previously assumed, we also assume that the E. gossypii cellular envi-258 ronment reflects its ancestral environment at the time of the introgression. A small number 259 of low expression genes appeared exapted, which is likely due to the mutation bias in the 260 endogenous genes matching the selection bias in the exogenous genes for G/C ending codons. 261 In general, low expression genes contribute little to the genetic load. In contrast, highly ex-262 pressed genes showed a large genetic load and still represent a significant genetic load. Our 263 Load estimates, therefore, indicate strong selection against introgressed sequences. 264

The large genetic load the exogenous genes represented at the time of the introgression indicates that the fixation of the introgression was a very unlikely event in a population with a large N_e as it is typical for yeasts. It is hard to contextualize the probability of this

introgression being fixed as we are not aware of any estimates of the frequency at which such large scale introgressions of genes with very different signatures of codon usage occur. 269 One example is Saccharomyces bayanus, a hybrid of Saccharomyces uvarum, Saccharomyces 270 cerevisiae, and Saccharomyces eubayanus. However, unlike with L. kluyveri and E. qossypii 271 the donor lineages show similar codon usage. Saccharomyces cerevisiae and Saccharomyces 272 eubayanus show a very strong correlation between selection bias $\Delta \eta$ of $\rho = 0.98$ and a strong 273 correlation between mutation bias ΔM of $\rho = 0.83$ We were unable to identify codon usage 274 for Saccharomyces uvarum. However, L. kluyveri diverged about 85 Mya ago from the rest 275 of the Lachancea clade. This represents between 10¹⁰ to 10¹¹ generations. Assuming for 276 yeasts typical effective population size on the order of 10^8 , we are left with 10^{18} to 10^{19} 277 opportunities for such an event to occur. In addition, the strong mutation bias towards 278 G/C ending codons in the exogenous genes may have contributed to the fixation of this 279 introgression. It is, on the other hand, also possible that despite their mismatch in codon 280 usage, the exogenous genes have represented a fitness increase due to external environmental 281 factors resulting in the fixation of the introgression. However, if that is the case one has 282 to wonder why recombination events did not limit the magnitude of the fixed introgression. 283 As previously mentioned, the exogenous region show a low recombination rate, potentially due to low homology with the rests of the genome. Alternatively, our results and population genetics principles suggest that the introgression has spread very rapidly as the time to fixation does not depend on the sign but only the magnitude of the selection coefficient s. 287 In conclusion, our results show the usefulness of the separation of mutation bias and se-288 lection bias and the importance of recognizing the presence of multiple cellular environments 289 in the study of codon usage. We also illustrate how a mechanistic model like ROC SEMPPR 290 and the quantitative estimates it provides can be used for more sophisticated hypothesis 291 testing in the future. In contrast to other approaches used to study codon usage like CAI 292 [Sharp, 1987] or tAI [?dos Reis et al., 2004], ROC SEMPPR is sensitive to differences in mu-293 tation bias. We highlight potential pitfalls when estimating codon preferences, as estimates can be biased by the signature of a second, historical cellular environment. In addition,
we show how quantitative estimates of mutation bias and selection relative to drift can be
obtained from codon data and used to infer the fitness cost of an introgression as well as its
history and potential future.

²⁹⁹ Text from Intro That Might Be Useful in Discussion

In general, the strength of selection on codon usage increases with gene expression [Ikemura, 1985, Gouy and Gautier, 1982]. Conversely, the impact of mutation bias on codon usage declines with gene expression. Thus, we can easily imagine that with increasing gene expression, codon usage shifts from a process dominated mutation to a process dominated by selection. Together, the mutation process favoring specific synonymous codons - or mutation bias - and the selection for translation efficiency scaled by gene expression and effective population size - or selection bias - shape codon usage in a genome.

ROC SEMPPR, which uses a bayesian MCMC method for model fitting, allows us to 307 quantify the contributions of mutation bias and selection on to the codon usage patterns of 308 a set of genes. ROC SEMPPR also allows us to predict a gene's average predicting protein 309 production rate based on its individual codon usage pattern with a precision comprable 310 to that of more direct empirical methods [Gilchrist et al., 2015b]. In addition, we show 311 that separately fitting ROC SEMPPR to endogenous and exogenous gene sets substantially 312 improves our ability to predict empirical estimates of protein synthesis rates over fitting 313 ROC to a combined dataset of endogenous and exogenous genes. 314

In order to identify a potential source lineage for *L. kluyveri*'s exogenous gene set we fit
ROC SEMPPR to the genomes of 38 yeast species. We then compared ROCs parameter
estimates of mutation bias and selection of *L. kluyveri*'s exogenous genes to these species
and found a strong correlation in only two species, *E. gossypii* and *C. dubliniensis*. We
also compared the synteny of *L. kluyveri*'s exogenous genes to these lineages. We found
strong synteny in a number of cases, most notably in *E. gossypii* but not *C. dubliniensis*.

As a result, we conclude that of the yeast species we examined, the E. gossypii lineage is most closely related to the the donor of L. kluyveri's exogenous genes. Assuming that E. gossypii's mutation bias is similar to the source of the exogenous genes, we estimated the introgression occurred approximately 6×10^8 generations ago using a model of exponential decay to describe the shift in mutation bias of the exogenous genes. Finally, we estimate the selective cost or genetic load of the exogenous genes due to codon usage mismatch using our estimates of the selection parameters from L. kluyveri's endogenous genes and the our estimates of the protein synthesis rate of the exongenous genes.

- Some genes pre-adapted to new environment
- Most genes not
 - Load estimate indicates strong selection against introgression sequences alone

• Explaining introgression

- Assuming introduction is continuous as it appears, indicates little recombination during spread
- Data suggests introgression spread quickly
 - Potential explanations
 - * Identified wrong source, though even current load is quite large.
 - * Major flaws in our calculation of fitness costs.
 - * Failure for positive selection on at amino acid or regulatory sequence at one or more loci, countering the selection on CU
 - * Introgression triggered speciation event, thus N_e was very small (< 100) so even if strongly selected against it still had a reasonable probability of fixing.

- * Unlikely event, but introgressions happen frequently. Note here mutation is actually an introgression event, not a nt change. Although pop gen predicts fixation probability is very low. However, pop gen also tells us that if such an unlikely fixation occurs, it is very likely to happen quickly. Thus, continuous nature of introgression also consistent with a rare, maladaptive fixation event.
- * Other adaptive effects of introgression seems most plausible, but since we don't know have reasonable estimates about frequently hybridiations occur nor accurate estimate of how frequent such introgressions fix, the maladaptive explanation is hard to evaluate.
- * Combination of most maladaptive, some adaptive alleles, and speciation could also be a feasible hypothesis.

Materials and Methods

Separating endogenous and exogenous genes

A GC-rich region was identified by Payen et al. [2009] in the *L. kluyveri* genome extending from position 1 to 989,693 of chromosome C. This region was later identified as an introgression by Friedrich et al. [2015]. We obtained the *L. kluyveri* genome from SGD Project http://www.yeastgenome.org/download-data/ (last accessed: 09-27-2014) and the annotation for *L. kluyveri* NRRL Y-12651 (assembly ASM14922v1) from NCBI (last accessed: 12-09-2014). We assigned 457 genes located on chromosome C with a location within the $\sim 1Mb$ window to the exogenous gene set. All other 4864 genes of the *L. kluyveri* genome were assigned to the exogenous genes. All genes could be uniquely assigned to one or the other gene set.

Model Fitting with ROC SEMPPR

ROC SEMPPR was fitted to each genome using AnaCoDa (0.1.1) [Landerer et al., 2018] and R (3.4.1). ROC SEMPPR was run from multiple starting values for at least 250,000 iterations, every 50th sample was collected to reduce autocorrelation. After manual inspection to verify that the MCMC had converged, parameter posterior means were estimated from the last 500 samples.

³⁷⁵ Comparing codon specific parameter estimates

Because our ΔM and $\Delta \eta$ are meaningful only for comparisons between synonymous codons, ROC SEMPPR returns mutation bias ΔM and selection bias $\Delta \eta$ parameter values relative to a reference codon. While ROC SEMPPR's choice of the reference codon is largely arbitrary, changes in the reference codon affect [NEED TO COMPLETE] To circumvent this issue, we express our estimates relative to the mean for each codon family.

Choice of reference codon does reorganize codon families coding for an amino acid relative to each other, therefore all parameter estimates are relative to the mean for each codon family.

$$\Delta M_{i,a}^c = \Delta M_{i,a} - \Delta \bar{M}_a \tag{1}$$

$$\Delta \eta_{i,a}^c = \Delta \eta_{i,a} - \bar{\Delta \eta_a} \tag{2}$$

Comparison of codon specific parameters (ΔM and $\Delta \eta$) was performed using the function lmodel2 in the R package lmodel2 (1.7.3) and R version 3.4.1. Type II regression was performed with re-centered parameter estimates, accounting for noise in dependent and independent variable.

385 Synteny

We obtained complete genome sequences from NCBI (last accessed: 02-05-2017). Genomes were aligned and checked for synteny using SyMAP (4.2) with default settings [Soderlund et al., 2006, 2011]. We assessed Synteny as percentage non-overlapping coverage of the exogenous gene region (Figure S3b).

Determining introgression timeline

We modeled the change in codon frequency over time using an exponential model for all two codon amino acids, and described the change in codon c_1 as

$$\frac{dc_1}{dt} = -\mu_{1,2}c_1 - \mu_{2,1}(1 - c_1) \tag{3}$$

where $\mu_{i,j}$ is the rate at which codon i mutates to codon j and c_1 is the frequency of the reference codon. Our estimates of ΔM_{endo} can be directly related to the steady state of equation 3.

$$\frac{\mu_{2,1}}{\mu_{1,2} + \mu_{2,1}} = \frac{1}{1 + \exp(\Delta M_{endo})} \tag{4}$$

Solving for $\mu_{1,2}$ gives us $\mu_{1,2} = \Delta M_{endo} \exp(\mu_{2,1})$ which allows us to rewrite and solve equation 3 as

$$c_1(t) = \frac{\exp(-t(1 + \Delta M_{endo})\mu_{2,1}) \exp(t(1 + \Delta M_{endo})\mu_{2,1}) + (1 + \Delta M_{endo})K}{1 + \Delta M_{endo}}$$
(5)

where K is

$$K = \frac{-1 + c_1(0) + c_1(0)\Delta M_{endo}}{1 + \Delta M_{endo}}$$
 (6)

Equation 5 was solved over time with a mutation rate $m_{2,1}$ of 3.8×10^{-10} per nucleotide per generation [Lang and Murray, 2008]. Initial codon frequencies $c_1(0)$ for each codon family where taken from our estimates of ΔM_{gos} from E.~gossypii. Current codon frequencies

for each codon family where taken from our estimates of ΔM from the exogenous genes.

Mathematica (9.0.1.0) [Inc.] was used to calculate the time t_{exo} it takes for the initial codon

frequencies $c_1(0)$ for each codon family to change to the current exogenous codon frequencies.

The same equation was used to determine the time t_{endo} at which the signal of the exogenous

cellular environment has decayed to within 1% of the endogenous environment.

399 Estimating Genetic Load

To estimate the fitness burden, we made three key assumptions. First, we assumed that the current exogenous amino acid composition of genes is representative of the replaced endogenous genes. Second, we assume that the currently observed cellular environment of $E.\ gossypii$ reflects the cellular environment that the exogenous genes experienced before transfer to $L.\ kluyveri$. Lastly, we assume that the difference in the efficacy of selection between the cellular environments of the source lineage and $L.\ kluyveri$ can be expressed as a scaling constant and that protein synthesis rate ϕ has not changed between the replaced endogenous and the introgressed exogenous genes.

Using estimates for $N_e = 1.36 \times 10^7$ [Wagner, 2005] for Saccharomyces paradoxus we scale our estimates of $\Delta \eta$ and define $\Delta \eta' = \frac{\Delta \eta}{N_e}$. We calculated the fitness burden each gene represents assuming additive fitness effects as

$$s_g = \sum_{i}^{C} -\kappa \phi_g \Delta \eta_i' n_{g,i} \tag{7}$$

where s_g is the selection against translation inefficiency. ϕ_g is the estimated protein synthesis rate for gene g in the exogenous gene set. $n_{g,i}$ is the codon count of each codon i in the codon set C for each gene g. κ is a constant, scaling the efficacy of selection between cellular environments. Like stated previously, our $\Delta \eta$ are relative to the mean of the codon family. We find that the fitness burden of the introgressed genes is minimized at $\kappa \sim 5$ (Figure S4b). Thus, we set $\kappa = 1$ if we calculate the s_g for the endogenous and the current exogenous

genes, and $\kappa = 5$ for s_g for the fitness burden at the time of introgression. Since we are unable to observe codon counts for the replaced endogenous genes and for the exogenous genes at the time of introgression, we calculate expected codon counts

$$E[n_{g,i}] = \frac{\exp(-\Delta M_i - \Delta \eta_i \phi_g)}{\sum_{j=1}^{C} \exp(-\Delta M_j - \Delta \eta_j \phi_g)} \times m_{a_i}$$
 (8)

 m_{a_i} is the number of occurrences of amino acid a that codon i codes for.

We report the genetic load of the introgression as $\Delta s = s_{Intro} - s_{Endo}$ where s_{Intro} is either the fitness burden at the time of the introgression or presently.
